# Further Examination of the Distribution of Individual <br> Income and Taxes Using a Consistent and <br> Comprehensive Measure of Income 

Tom Petska and Mike Strudler, Internal Revenue Service, and Ryan Petska, Florida State University

Different approaches have been used to measure the distribution of individual income over time. Survey data, such as those from the U.S. Census Bureau's Current Population Survey (CPS) and Survey of Income and Program Participation (SIPP), have been compiled with detailed enumeration, but underreporting of incomes, inadequate coverage at the highest income levels, and omission of a key income type jeopardize the validity of results. Administrative records, such as individual income tax returns, may be less susceptible to underreporting of income but exclude certain nontaxable income types. In addition, estimates of change can be unreliable in periods when the tax law has been substantially altered. Record linkage studies have capitalized on the advantages of both approaches, but are costly and severely restricted by the laws governing interagency data sharing.

This paper is the third in a series examining trends in the distribution of individual incomes and tax burdens based on a consistent and comprehensive measure of income derived from individual income tax returns $[1,2]$. In the two previous papers, we demonstrated that the shares of income accounted for by the highest in-come-size classes have clearly increased over time, although some of this increase was tempered by corresponding increases in the shares of taxes paid by these groups. We also demonstrated the superiority of our comprehensive and consistent income measure, the 1979 Retrospective Income Concept, particularly in periods of tax reform.

In this paper, we continue this analysis of individual income and tax distributions. The paper has four sections. In the first section, we briefly summarize this measure of individual income derived as a "retrospective concept" from individual income tax returns. In the second section, we present the results of our analysis of time series data on individual incomes and taxes. Next, we estimate Lorenz curves and compute Gini coefficients from these data and summarize our findings. Finally, data limitations, results, and conclusions are presented.

## - Derivation of the 1979 Retrospective Income Concept

The tax laws of the 1980's and 1990's made significant changes to both the tax rates and definitions of taxable income. The tax reforms of 1981 and 1986 significantly lowered individual income tax rates, and the latter also substantially broadened the income tax base. The tax law changes effective for 1991 and 1993 initiated rising individual income tax rates and further modifications to the definition of taxable income [1,2]. Law changes effective for 1997 lowered the maximum tax rate on capital gains. With all of these changes, the questions that arise are what has happened to the distribution of individual income and the shares of taxes paid by the various income-size classes?

In order to analyze changes in income and taxes over time, consistent definitions of income and taxes must be used. However, the Internal Revenue Code has been substantially changed in the last 19 years-both the concept of taxable income and the tax rate schedules have been significantly altered. The most commonly used income concept available from Federal income tax returns, Adjusted Gross Income (AGI), was designed to facilitate tax administration, and its definition has changed over time to reflect modifications to the Internal Revenue Code. These changes made it difficult to use AGI for inter-temporal comparisons of income.

For this reason, an income definition that would be both comprehensive and consistent over time was developed [3,4,5]. The 1979 Retrospective Income Concept was designed to include the same income and deduction items from items available on Federal individual income tax returns. Tax Years 1979 through 1986 were used as base years to identify the income and deduction items, and the concept was subsequently applied to later years by including the same income components common to all years.

As shown in Figure A, the calculation of the 1979

Retrospective Income Concept includes several items partially excluded from AGI for the base years, the largest of which was capital gains [1,2]. The full amounts of all capital gains, as well as all dividends and unemployment compensation, were included in the income calculation. Total pensions, annuities, IRA distributions,

and rollovers were added, including nontaxable portions that were excluded from AGI. Social Security benefits were omitted because they were not reported on tax returns until 1984. Also, any depreciation in excess of straight-line depreciation, which was subtracted in computing AGI, was added back [1,2].

For this study, retrospective income was computed for all individual income tax returns in the annual Statistics of Income (SOI) sample files for the period 1979 through 1997. Loss returns were excluded and the tax returns were tabulated into income-size classes based on the size of retrospective income and ranked from highest to lowest. Percentile thresholds were interpolated within the income-size classes for the following groups: the top 1 percent; 1-to-5 percent; 5-to-10 percent; 10-to-20 percent; 20-to-40 percent; 40-to-60 percent; 60-to- 80 percent; and the bottom 20 percent [6,7,8]. For each size class, the number of returns and the amounts of retrospective income and taxes paid were compiled. From these data, income and tax shares and the average taxes were computed for each size class for all years.

Table 1 presents the interpolated income thresholds for all of the years. Table 2 shows the number of returns for each size class, and Tables 3 and 4 present the amounts of aggregate retrospective income and taxes for each size class, respectively.

## The Distribution of Income and Taxes

With this database, we sought to answer the following questions-have the distribution of individual incomes (i.e., income shares), the distribution of taxes (i.e., tax shares), and the average effective tax rates (i.e., tax burdens) changed over time? As a first look at the data, we examined the income thresholds of the bottom (or entry level) of each income-size class and a clear pattern emerged. While all of the income thresholds have increased over time, the largest increases in absolute terms, and on a percentage basis, were with the highest income-size classes.

For example, while \$79,679 of retrospective income were needed to enter the top 1-percent size class for 1979,
\$269,414 were needed for entry into this size class for 1997, an increase of 238 percent. But for the top 20 percent, the threshold increased by 123 percent, and, for the bottom 20 percent, the increase was only 92 percent. Since much of these increases are attributable to inflation, we computed constant dollar thresholds, using the Consumer Price Index, which are plotted in Figure B and shown in Table 5 [9].

What is most striking about these data are the changes between 1979 and 1997 for the various incomesize percentile thresholds. For example, the threshold for the top 1 percent rose from $\$ 109,751$ for 1979 to $\$ 167,859$ for 1997 , an increase of nearly 53 percent. However, the thresholds for each lower percentile class show smaller increases in the 19 -year period; the top 20-percentile threshold increased only 1 percent, and the 40 -percent and all lower thresholds declined in inflation-adjusted dollars, with larger percentage reduc-
tions for the smaller income-size classes.

## Income shares

The data on income shares by percentile-size classes are provided in Table 6 and summarized in Figure C for 1979 through 1997. The share of income accounted for by the top 1 percent of the income distribution has climbed steadily from a low of 9.58 percent for 1979 to a high of 17.94 percent for 1997. While this increase is quite steady, there were some significantly large jumps, particularly for 1986, due to a surge in capital gains realizations after the passage, but before implementation, of the Tax Reform Act of 1986 (TRA). The top 1-percent share also increased for 1995 through 1997. Notable declines in the top 1-percent share occurred in the recession years of 1981 and 1990-1991.

This pattern of an increasing share of total income

Figure B--Constant Dollar Income Thresholds, 1979-1997

Figure C--Income Shares by Income Percentile Size-Classes, 1979-1997

is mirrored in the 1 -to- 5 percent class and the 5 -to- 10 percent class, but to a considerably lesser degree. For the former group, the income share increased from 12.60 percent to 14.91 percent, while for the latter, the share barely increased from 10.89 percent to 11.00 percent in this period. All of the other lower percentile-size classes, from the 10 -to- 20 percent class to the four lowest quintiles, show declines in shares of total income over the 19 -year period. Overall, the top quintile increased its share of total income from 50 percent for 1979 to nearly 60 percent for 1997 .

## Tax shares

Data on tax shares by the percentile-size classes are shown in Table 7 and summarized in Figure D [10]. The share of taxes accounted for by the top 1-percent group also climbed steadily in this period, from initially at 19.75 percent for 1979 , then declining to a low of 17.42 per-
cent for 1981, before rising to 32.58 percent for 1997. As with incomes, there were some unusually large increases, particularly for 1986, but also for 1982, 1983, 1988, 1992, 1993 (the first year of the 39.6-percent top marginal tax rate), 1995 and 1996. One common feature for all these years was that net capital gains reported in AGI showed double-digit growth from the previous year [3,5].

The 1-to-5 percent size class exhibited relatively modest change in its share of taxes, increasing from 17.53 percent to 18.79 percent in the period. The 5 -to10 percent class, and all lower income-size classes, had declining shares of total tax [11]. The top quintile increased its share of taxes from 66.82 percent to 76.40 percent of the total in the 1979 to 1997 period.

Average tax rates

Figure E--Average Tax Rates for Income Percentile Size Classes,
1979-1997

1979198019811982198319841985198619871988198919901991199219931994199519961997
Tax Year

Average tax rates by income-size class are presented in Figure E and Table 8. What is most striking about these data is that the levels of the average tax burdens increase with income size in all years. The progressivity of the individual income tax system is clearly demonstrated.

Despite the fact that the overall average tax rate increased slightly between 1979 and 1997 (i.e., rising from 13.96 percent to 14.30 percent), the average rate for all but the very lowest size class actually declined [11]. While this at first appears to be inconsistent, it is clear how this did in fact occur - over time, the proportion of income has shifted to the upper levels of the income distribution, where it is taxed at higher rates.

In examining the average tax data by income size, three distinct periods emerge. First, the average tax rates were generally climbing up to the implementation of the Economic Recovery Tax Act (ERTA) effective for 1982. This was an inflationary period, and prior to indexing of personal exemptions, the standard deduction, and tax brackets, which caused many taxpayers to face higher tax rates. (Indexing became a permanent part of the tax law for Tax Year 1985 [3].) Also, this period marked the recovery from the recession in the early 1980 's.

Similarly, average taxes also climbed in the period after 1992, the period affected by the Omnibus Budget and Reconciliation Act (OBRA). This was not surprising for the highest income-size classes, ones affected by the OBRA-initiated 39.6-percent top marginal tax rate, but the average tax rate increases are also evident in the smaller income-size classes for most years in the 1993 to 1997 period as well.

For the majority of intervening years (i.e., 1982 through 1992), average tax rates generally declined by small amounts for most income-size classes, although the period surrounding the implementation of the 1986 Tax Reform Act (TRA) gave rise to small increases in some classes. Despite the substantial base broadening and rate lowering initiated by TRA, for most incomesize classes, the changes to average rates were fairly small. However, it should be kept in mind that individuals can and do move between income-size classes.

The rates for the top 1 percent clearly show the effects of the 1986 capital gains realizations, in anticipation of the ending of the 60-percent long-term gains exclusion, which began in 1987. The average tax rate for this income-size class dropped for 1986, but rose sharply for 1987, before dropping again for each of the next three years.

To assess what happened, it is important to look at the underlying data. The substantial increase in capital gains realizations for 1986 swelled the aggregate income and tax amounts for upper income classes and also raised the income thresholds of these top classes. However, since much of the increase in income for these size classes was from net long-term capital gains, which had a maximum effective tax rate of 20 percent (i.e., a 50percent maximum marginal tax rate combined with the 60-percent exclusion), it is not surprising that the average tax rate for these top size classes declined.

Interestingly, the average tax increases which predominate in the 1993-1997 period have one very noticeable exception - the average rate for the top 1-percent size class declined from 26.98 to 25.96 between 1996 and 1997. We believe that effect is the direct result of the reduction in the top capital gains tax rate, from 28.0 to 20.0 percent, which began in May 1997.

## Lorenz and Gini Analysis of the Distributions

To further analyze the data, we estimated Lorenz curves and computed Gini coefficients for all years. The Lorenz curve is a cumulative aggregation of income from lowest to highest, expressed on a percentage basis. To construct the Lorenz curves, we re-ordered the percentile classes from lowest to highest and used the income thresholds as "plotting points" to fit a series of third-order regression equations for each of the 19 years, both before- and after-taxes.

Lorenz curves for 1979 and 1997 are plotted in Figure F. The 45-degree diagonal or "identity function" in the figure represents the unlikely situation of everyone having equal amounts of income. In this scenario, 10 percent of the tax return filers would account for 10 percent of the income, as would 50 percent, 90 percent, etc. Clearly, although such a situation is a virtual impossibility, it is a

useful yardstick by which to measure the degree of income inequality.

The Lorenz curve for 1979 is above and to the left of that for 1997 - this is because for each cumulative percent of tax returns (as measured on the horizontal axis), the cumulative percent of income for 1979 (measured on the vertical axis) exceeds that for 1997. Clearly this is a situation of less income inequality for 1979 , which is also evident from the income share data in Figure C and Table 6.

Once the Lorenz curves were estimated for all years, Gini coefficients were calculated. Intuitively, the Gini coefficient is a measure of the degree of inequalitythat is, a higher Gini value represents more inequality. From Figure F, the Gini coefficient is measured as follows:

$$
\text { Gini coefficient }=\text { Area A } /(\text { Area A }+ \text { Area B }) * 100
$$

that is, the Gini coefficient is the estimated area beneath the 45-degree diagonal but above the Lorenz curve (an amount of "inequality") expressed as a percentage of the entire area below the 45-degree diagonal. Thus, if the Lorenz curve were bowed down and to the right,

Area A would increase thereby increasing the Gini coefficient.

As shown in Figure G, Gini coefficients for all 19 years were estimated for both before- and after-tax income distributions. The Gini coefficients increased throughout the 19 -year period signifying rising levels of inequality for both the pre- and post-tax distributions. This result was not unexpected since it parallels the rising shares of income accruing to the highest incomesize classes. Over this period, the before-tax Gini coefficient value increased from 0.473 to 0.564 ( 19.2 percent), while the after-tax Gini value increased from 0.442 to 0.534 for a slightly higher percentage increase (20.8 percent).

Figure G-Gini Coefficients for Retrospective Income, Before and After Taxes, 1979 - 1997

|  | -Gini Coefficients <br> Year |  |  | Before tax | Percent |
| :--- | :--- | :--- | :--- | :--- | :---: |

| 1987 | 0.517 | 0.490 | 0.027 | 5.2 |  |
| 1988 | 0.535 | 0.509 | 0.026 | 4.9 |  |
| 1989 | 0.533 | 0.508 | 0.025 | 4.7 |  |
| 1990 | 0.532 | 0.508 | 0.024 | 4.5 |  |
| 1991 | 0.529 | 0.504 | 0.025 | 4.7 |  |
| 1992 | 0.538 | 0.512 | 0.026 | 4.8 |  |
| 1993 | 0.536 | 0.508 | 0.028 | 5.2 |  |
| 1994 | 0.537 | 0.508 | 0.029 | 5.4 |  |
| 1995 | 0.545 | 0.515 | 0.030 | 5.5 |  |
| 1996 | 0.557 | 0.526 | 0.031 | 5.6 |  |
| 1997 | 0.564 | 0.534 | 0.030 | 5.3 |  |

So what has been the effect of the Federal tax system on the size and change over time of the Gini coefficient values? One way of looking at this question is to compare the before- and after-tax Gini values. Although this is not a perfect measure, since the tax law can also
affect the pre-tax income distribution, it is still a useful comparison [12].

From this comparison, two conclusions are clear. First, Federal income taxation decreases the Gini coefficients for all years. This is not surprising in that the tax rate structure is progressive, with average rates rising with higher incomes, so after-tax income is more evenly distributed than before-tax income. A second question is whether the relationship between the beforetax and after-tax Gini coefficient values has changed over time. From Figure F, the after-tax series closely parallels the before-tax series, with reductions in the value of the Gini coefficient ranging from 0.024 to 0.031 . The largest differences, which denote the largest redistributive effect of the Federal tax system, are for 19791981 and 1994-1997, periods of relatively high marginal tax rates [13].

But to investigate further, the percentage reduction to the before-tax Gini values were computed and are shown as the fourth column in the figure. These percentage changes in the Gini coefficient values, a "redistributive effect," show a decline ranging from 4.5 to 6.6 percent. As for the differences, the largest percentage changes are for the earliest and latest years, periods when the marginal tax rates were high [13]. The largest percentage reduction was for 1979 , but the size of the reduction generally declined until 1986, fluctuated at relatively low levels between 1986 and 1992, then increased from 1993 to 1996. However, coinciding with the capital gains tax reduction for 1997, the percentage change again declined for 1997.

So what does this all mean? First, the high marginal tax rates prior to 1982 appear to have had a significant redistributive effect. But, beginning with the tax rate reductions for 1982, this redistributive effect began to decline up to the period immediately prior to the 1986 Tax Reform Act (TRA). Although TRA became effective for 1987, a surge in late 1986 capital gains realizations (to take advantage of the 60-percent longterm capital gains exclusion) effectively lowered the average tax rate for the highest income groups thereby lessening the redistributive effect.

For the post-TRA period, the redistributive effect
was relatively low, and it didn't begin to increase until the initiation of the 39.6-percent tax bracket for 1993. But for 1997, with continuation of the 39.6 - percent rate but with a lowering of the maximum tax rate on capital gains, the redistributive effect again declined. Overall, it appears that the redistributive effect was higher in years that had relatively high marginal tax rates for both ordinary and capital gain income.

To further examine the Gini coefficients over time, we surveyed the literature for other estimates of Gini values. While this work is clearly in its infancy, one finding was that our estimates generally exceeded those of other researchers, particularly those based primarily on Census income concepts [14]. If each of these is a valid measure of its respective population, the questions that arise are "What are the reason or reasons for the differences?" and "Which Gini coefficient series is most valid?"

As stated earlier, distributional studies based on Census CPS and SIPP data clearly have more complete coverage of transfer income, which is primarily received at the lower end of the income distribution. So from this standpoint, the Census-based data have a clear advantage. However, the tax data are based on substantially more complete sampling at the highest income levels and, as our data show, much of the increased inequality is attributable to changes to the income shares of these groups. Further, the tax data have one other important difference that primarily affects the incomes of the upper income groups - the inclusion of realized capital gains.

Economists generally agree that an ideal measure of income would consist of consumption plus any change in net worth [15]. Implementing such a concept on a current study of income distribution would be very difficult, since changes in asset values are neither widely compiled nor easily measured. So, while the Censusbased studies generally exclude all capital gains, our study and most others based on tax return data generally include "realized" capital gains, a less-than-ideal proxy for all capital gains. However, despite its shortcomings, some estimate of capital income is essential in measuring the income of high income-size groups. And, since capital gains are so highly concentrated at the up-
per end of the income distribution, it is not surprising that our income distribution measures more concentration at higher income values, which result in higher estimated Gini coefficient values.

Another issue in Gini estimation concerns the unit of measurement-that is, whether the unit is an individual, family, or household, for example. The tax data are not really any of the above, per se. They are a combination of individual and family, based on the filing status elected by the taxpayer. Beginning with 1987, a primary taxpayer was required to list the name and Social Security Number of any dependents claimed as personal exemptions, even if those dependents had to file their own tax returns. So, even though it would be possible to link such tax returns and aggregate their "family income," the retrospective income concept does not currently include this, treating such dependents as separate taxpayers. As a result, such dependent taxpayers would appear to be low-income, unrelated individuals, thereby giving rise to more inequality and higher Gini coefficient values, ceteris paribus.

To attempt to ascertain some measure of this effect, we excluded the returns of dependents claimed on a tax return who also filed their own tax returns. And while this comparison was only for 1 year, we believe it gives a reasonable first look at the degree to which this phenomenon affects estimated Gini coefficient values. For 1997, by excluding these dependents, we calculated a decrease in the Gini coefficient value of 0.03 , a 5 percent decrease in inequality. So clearly, the inclusion of the tax returns of these dependents does raise the Gini values, but our initial examination of this effect seems to indicate that it is quite small.

## Data Sources, Limitations, and Conclusions

The Statistics of Income (SOI) Division of IRS produces annual studies of individual income and taxes by sampling and compiling data from Forms 1040, Individual Income Tax Return [3]. Returns were selected as part of random, stratified cross-sectional samples. For this study, returns from these samples were then tabulated into size classes of retrospective income, and the
percentile thresholds are estimated by interpolation [6,7].
Although the retrospective income concept is a consistent measure for inter-year income comparisons, it has shortcomings. First, persons with incomes below the filing thresholds are not required to file tax returns and are excluded from the database. To the extent that the size of the nonfiling population changes from year-to-year, such comparisons can be a cause for concern. However, for the period of this study, we feel that this is not a major shortcoming, but one that still needs further investigation. Since the focus of this study has been on the upper tail of the income distribution, minor changes in the lowest end of the filing population would not be expected to influence the top income-size classes by much.

Our data are based on successive cross-sectional samples and are not a panel. In the underlying microdata, individuals can move in and out of annual studies, as well as across the thresholds of income-size classes. Also, as previously noted, the database is derived from individual tax return filings and is not a family income concept. No attempt was made to link the income of codependents. Cash and in-kind public assistance, as well as earned income tax credit refunds, are also excluded from retrospective income. Further, while Federal individual income taxes are included, Social Security (FICA) taxes, corporation income taxes, and excise taxes are not.

Overall, we believe that retrospective income is an outstanding measure even though it does have limitations in coverage and scope. Some conclusions can be drawn from examination of these data. Both the income and tax shares of the top 1-percent size class increased substantially in this period. The income share of the 1-to- 10 percent group increased modestly, but its share of taxes remained essentially unchanged. The income share of the top quintile increased from 50 percent to nearly 60 percent of the total, and its share of taxes increased from two-thirds to over three-fourths of the total.

The bottom four quintiles all had declining shares of total income between 1979 and 1997. Further, while the declines in the percentage shares of total income decreased with decreasing income size, the percentage
changes in the shares were actually largest with the lowest quintiles. Clearly, the pre-tax income shares have shifted upward. However, the declining shares of pretax income of the bottom quintiles were somewhat mitigated by their declining shares of taxes.

Concerning average tax rates, most income-size classes had declining average rates between 1979 and 1997. These declines would have been even larger except that all size classes exhibit increases between 1993 and 1996. The only group for which average taxes declined for 1997 was for the top 1-percent size class. We attribute this decline to the reduced tax rate available for capital gains income. Overall, the levels of average taxes clearly increase with increasing income size, which is conclusive evidence of tax progressivity.

In summary, the upper tail of the income distribution has increased its share of total income at the expense of the lower income-size classes. However, this rise in inequality in pre-tax income has been somewhat offset by increases in taxes paid by the top income-size classes, particularly from the tax rate increases for 1993 through 1996. However, it remains to be seen if the reduction in the average tax rate for the top 1 percent for 1997, which we attribute to the reduction in the maximum capital gains tax rate, is a sign that the Federal income tax system will once again have a somewhat diminished effect in reducing income inequality.

## Acknowledgments

Tom Petska is Chief, Special Studies Branch, Statistics of Income (SOI) Division of the Internal Revenue Service, and Mike Strudler is Senior Economist, Individual Statistics Branch, SOI Division. Ryan Petska was a Summer Intern and Mathematical Statistician in the Individual Statistics Branch, SOI Division, and is currently a graduate student in the Department of Statistics, Florida State University, Tallahassee, FL.

The authors would like to thank several colleagues who made important contributions to this study. Mario Fernandez of the Individual Statistics Branch, SOI Division, computed retrospective income from the SOI individual income files and produced detailed tabulations by the retrospective income-size classes. Lock Oh,
recently retired from the SOI Special Studies Branch, interpolated the percentile thresholds and compiled the data for each percentile size class. Janice Coleman, also of the SOI Special Studies Branch, provided help with graphics. Finally, Beth Kilss and James Dalton provided invaluable pre-publication review of the manuscript. Any errors that remain are solely the responsibility of the authors.

[7] Oh, H. Lock and Scheuren, Fritz, "Osculatory Interpolations Revisited," 1987 Proceedings of the

American Statistical Association, Section on Statistical Computing.
[8] After the original estimates, we broke out additional subgroups within the top 1-percent incomesize class by increasing the stratification of retrospective income and re-computing the interpolations.
[9] The CPI-U from the U.S. Department of Labor, Monthly Labor Review, was used for deflation of the income thresholds.
[10] Taxes, taxes paid, tax liabilities, tax shares, and average or effective tax rates are based on income tax, defined as income tax after credits plus alternative minimum tax less the nonrefundable portion of the earned income credit.
[11] The one exception is for the lowest quintile for Tax Year 1979. The Revenue Act of 1978 increased both exemption and zero-bracket amounts so that many low income tax returns became nontaxable. For 1979, many low-income taxpayers still had to file a return in order to receive refunds. Once they had been nontaxable for one year, these individuals could file Forms W-4 instructing their employers to stop withholding income taxes. Thus, after 1979, many taxpayers with low incomes were no longer part of the individual taxpayer filing
population.
[12] A comparison of the before- and after-tax Gini coefficient values does not exclusively measure the effects of the tax system in that the tax laws can also affect before-tax income. For example, capital gain realizations have been shown to be sensitive to the tax rates so the tax system affects both the before- and after-tax income distributions.
[13] The period 1982-86 also had relatively high tax rates for ordinary income although it was lower than the preceding years.
[14] See, for example, Plotnick, Robert D.; Smolensky, Eugene; Evenhouse, Eirik; and Reilly, Siobhan, "The Twentieth Century Record of Inequality and Poverty in the United States," Institute for Research on Poverty Discussion Paper no. 1166-98, 1998.
[15] See, for example, the following for discussions on measuring economic income: Haig, Robert Murray, "The Concept of Income-Economic and Legal Aspects," The Federal Income Tax, Columbia University Press, 1921; Simons, Henry C., Personal Income Taxation: The Definition of Income as a Problem of Fiscal Policy, Chicago University Press, 1938; and Nelson, Susan, "Family Economic Income and Other Income Concepts Used in Analyzing Tax Reform," Compendium of Tax Research, 1986, Office of Tax Analysis, U.S. Department of the Treasury, 1987.
